Relation Between INL and ACPR of RF DACs
Seyed-Mehrdad Babamir, Member, IEEE, and Behzad Razavi, Fellow, IEEE

Abstract—The integral nonlinearity of digital-to-analog converters manifests itself as adjacent-channel power in RF transmitters. This paper derives compact equations relating these two quantities and verifies the results by simulations. Both current-steering and switched-mode architectures are analyzed.

Index Terms—RF DAC nonlinearity, phase distortion, AM/AM and AM/PM conversion, ACPR relation, INL.

I. INTRODUCTION

Digital RF transmitters have become popular for their numerous advantages over their analog counterparts [1], [2], [3], [4], [5], [6], [7], [8], [9]. A digital transmitter (TX) dispenses with most of the analog functions and contains only one analog port, namely, its output. Of course, such an approach relies on a high-speed, high-linearity digital-to-analog converters (DACs). The DAC’s output settling must be commensurate with the carrier frequency, and its linearity is dictated by the tolerable distortion of the desired signal and/or the adjacent-channel power ratio (ACPR). The latter proves particularly challenging in cellular applications such as the Long-Term Evolution (LTE) standard.

The nonlinearity and spurious-free dynamic range (SFDR) of DACs have been studied extensively [10], [11], [12], [13], [14], [15]. This paper focuses on the relation between the DAC nonlinearity and ACPR. The objective is to provide compact equations that help the designer decide how to select the DAC unit cells and how much residual integral nonlinearity (INL) can be tolerated after correction techniques such as predistortion are applied.

Section II deals with the nonlinearity analysis of current-steering DACs and Section III relates their INL and ACPR. Section IV studies these DACs’ behavior if the input is approximated by white noise, and Section V examines the effect of phase distortion. Section VI repeats the computation for switched-mode architectures.

II. NONLINEARITY OF CURRENT-MODE RF DACS

In this section, we focus on RF DACs that employ current switching so as to deliver a high power to the antenna [5], [6], [7], [8]. Figure 1 shows a common topology for a unit cell of the DAC [7] where the cascode transistors allow large output voltage swings without stressing $M_1$ and $M_2$. The principal source of INL in this arrangement is the finite output resistance of each unit. The resulting nonlinearity is typically excessive, requiring some form of correction, e.g., predistortion [16].

As a design example, we choose 256 unit cells each having a current of 1.54 mA and an output resistance of 1.2 kΩ. We also assume the matching network transforms the 50-Ω antenna resistance to 3.5 Ω. Such a design delivers a peak power of about 20 dBm.

For our analysis in subsequent sections, we wish to approximate the RF DAC static characteristic by a polynomial. To this end, we first consider a baseband DAC (without upconversion). The INL is simulated by applying a digital ramp to the input,
finding the output values, passing a straight line between the end points of the characteristic, and computing the difference between the two.

A. Baseband Model

Assuming that the DAC employs \( N \) identical units and that \( N \) is an even number, let us begin with the equivalent circuit depicted in Fig. 2(a), where each unit is modeled by a current source equal to \( I_0 \) and an output resistance equal to \( r_O \). The total differential load resistance presented by the output matching network is \( 2R_L \). We assume \( m \) current switches are active on the left and \( N - m \) on the right. Since this DAC is differential, \( V_{out} \) is an odd function of \( m \) around \( N/2 \), a reasonable assumption in view of the small mismatches between the two sides. It can be shown that

\[
V_{out} = -I_0 R_L \frac{(N - 2m)r_O^2}{(m R_L + r_O)[(N - m)R_L + r_O]}, \tag{1}
\]

hence

\[
V_{out}(m = 0) = -I_0 R_L \frac{N^2}{r_O(NR_L + r_O)} \tag{2}
\]

\[
= -I_0 \frac{n R_L + r_O}{n R_L + r_O} \tag{3}
\]

and \( V_{out}(m = N) = I_0[r_O][(NR_L)] \) due to the odd symmetry around \( m = N/2 \) [Fig. 2(b)]. Since the INL and the slope of this characteristic are invariant to \( m \), we shift the plot to the left by \( N/2 \) and introduce a new variable \( k = m - N/2 \) [Fig. 2(c)].

We surmise that this symmetric characteristic can be approximated by a third-order polynomial of the form

\[
V_{out} = \alpha_1 k + \alpha_3 k^3. \tag{5}
\]

For \( k = \pm N/2 \), we have

\[
\pm \alpha_1 \frac{N^2}{2} \pm \alpha_3 \frac{N^3}{8} = \pm I_0[r_O][(NR_L)]. \tag{6}
\]

We must impose one more constraint, e.g., the value of the polynomial must be equal to that of the actual characteristic at \( m = N/4 \) and \( m = 3N/4 \) in Fig. 2(b) or, equivalently, at \( k = -N/4 \) and \( k = +N/4 \) in Fig. 2(c). It follows that

\[
\alpha_1 \left( \frac{N}{4} \right)^3 + \alpha_3 \left( \frac{N}{4} \right) = -I_0 R_L \frac{(N/2)r_O^2}{(N/4 R_L + r_O)}, \tag{7}
\]

Equations (6) and (7) must be solved to obtain \( \alpha_1 \) and \( \alpha_3 \).

The polynomial approximation readily allows us to calculate the maximum INL. For an input range from \( k = -N/2 \) to \( +N/2 \), we pass a straight line through the end points, subtract it from the polynomial, and differentiate the result with respect to \( k \). It follows that \( \text{INL}_{max} = |\alpha_3| N^3/12\sqrt{3} \). The maximum differential output voltage is equal to \( \pm \alpha_3(N/2)^3 + \pm \alpha_1(N/2) \), which is close to \( \pm \alpha_1(N/2) \) if the peak INL is less than about 4%. We normalize \( \text{INL}_{max} \) to this value:

\[
\text{INL}_{max,n} = \frac{1}{6\sqrt{3}} \alpha_1 N^2. \tag{8}
\]

For the assumption \( |\alpha_3| (N/2)^3 \ll |\alpha_1| (N/2) \) to be valid, we have \( |\alpha_3/\alpha_1| N^2/(6\sqrt{3}) \ll 4/(6\sqrt{3}) \approx 0.38 \), concluding that \( \text{INL}_{max,n} \) should be less than about 3.8%. For the unit cell design values mentioned above, we have \( \alpha_1 = 5.3 \times 10^{-3} \) V and \( \alpha_3 = -1.7 \times 10^{-8} \) V for \( N = 256 \). In this case, the peak INL is about 2.1%. These values are computed by first finding the unit cell’s \( r_O \) (= 1.2 k\Omega) and then using Eqs. (6) and (7). Figure 3 plots the normalized INL of this DAC.

The effect of random mismatches within the DAC typically falls well below due to the output impedance. Since large widths must be chosen for the unit output resistance so as to deliver the desired power, the matching among them (which is proportional to the transistors’ channel area) is generally precise. As an example, an 8-bit design in 28-nm technology providing a +20-dBm output requires a unit width of roughly 45 \( \mu \)m, which exhibits a threshold voltage mismatch, \( \Delta V_{TH} = A_{VTH}/\sqrt{WL} \) [17], of 3.5 mV with \( A_{VTH} = 4 \) mV \( \cdot \) \( \mu \)m. We have designed an 8-bit DAC using the cell shown in Fig. 1 for an output power of +20-dBm. We have \( W_{1,4} = 45 \mu \)m, \( W_{2,5} = 14 \mu \)m. Figure 3 plots the simulated INL profile of the circuit, revealing a maximum value of 2.1%. Moreover, Monte Carlo simulations indicate that the INL rises to 2.3% when the mismatches are included. The above transistor-level simulations have been carried out with transition times of 20 ps for \( D_n \) and \( \overline{D_n} \). No glitches are observed at the output.

According to transistor-level simulations, the memoryless model of Fig. 2(a) is fairly accurate for carrier frequencies up to several gigahertz in 28-nm technology. Beyond this range, it is necessary to proceed with the AM/AM and AM/PM models described in Section V.

B. Band-Pass Model

The INL results obtained in the previous section must be revised for a band-pass DAC. The principal difference between baseband and band-pass DAC designs is that the latter turns the unit current sources on and off at the LO frequency. Thus, the output conductance of each unit toggles between \( 1/r_O \) and zero, presenting an “average” conductance equal to \( 1/(2r_O) \). We therefore expect that the \( r_O \) terms in Eq. (1) must be replaced with \( 2r_O \) so as to model the band-pass DAC. We prove this point in Appendix I.

With the aid of these observations, we now rewrite (6) and (7) as

\[
\frac{N}{2} \alpha_1 + \frac{N^3}{8} \alpha_3 = \pm I_0[r_O][(NR_L)]. \tag{9}
\]
\[ a_1 \left( \frac{N}{4} \right) + a_3 \left( \frac{N}{4} \right)^3 = \frac{-I_0 R_L (N/2) (2r_O)^2}{\left( \frac{N}{4} R_L + 2r_O \right) \left( \frac{3N}{4} R_L + 2r_O \right)}. \] (10)

These equations are readily solved to obtain \( a_1 \) and \( a_3 \) for the band-pass DAC.

### III. INL-ACPR Relation for Current-Mode RF DACs

To derive compact equations for the relation between INL\(_{\text{max},n}\) and ACPR, we wish to approximate the band-pass modulated RF signal by simpler functions. We surmise that a two-tone or four-tone representation may suffice.

Let us consider a two-tone model of the signal:

\[ x(t) = A \cos \omega_1 t + A \cos \omega_2 t, \] (11)

where \( \omega_1 \) and \( \omega_2 \) lie in the desired channel, but \( 2\omega_1 - \omega_2 \) and \( 2\omega_2 - \omega_1 \) in the adjacent ones. We select \( A = N/4 \) to avoid DAC input overrange. At the output, the fundamental and third-order intermodulation components exhibit amplitudes equal to \( a_1 A + (9/4)a_3 A^3 \) and \( (3/4)a_3 A^3 \), respectively. The ACPR is given by the ratio of their powers:

\[ \text{ACPR} = \frac{(9/16)a_3^2 A^6}{2(a_1 A + (9/4)a_3 A^3)^2} = \frac{(9/16)(a_3/a_1)^2 A^4}{2[1 + (9/4)(a_3/a_1)^2]}. \] (12)

Also, with \( A = N/4 \), Eq. (8) yields

\[ \text{INL}_{\text{max},n} = \frac{8}{3\sqrt{3}} \frac{a_3}{a_1} A^2, \] (13)

which, upon substitution in Eq. (13), leads to

\[ \text{ACPR} = \frac{(35/210)\text{INL}_{\text{max},n}^2}{2[1 - (27\sqrt{3}/32)\text{INL}_{\text{max},n}]} \] (14)

For example, an ACPR of \(-33\) dB for Wideband CDMA (WCDMA) [18] requires \( \text{INL}_{\text{max},n} < 6.5\% \). This value reveals that \( (27\sqrt{3}/32)\text{INL}_{\text{max},n} \) is typically much less than unity (after predistortion or other linearization techniques), allowing a simpler expression:

\[ \text{ACPR} \approx 0.119 \text{INL}_{\text{max},n}^2. \] (15)

Similarly, we can also obtain the gain compression at the maximum point, in terms of \( \text{INL}_{\text{max},n} \). The gain compression at this point is given by

\[ G_c = \frac{2(a_1 A + (9/4)a_3 A^3)^2}{2(a_1 A)^2} = \left( 1 - \frac{27\sqrt{3}}{32} \text{INL}_{\text{max},n} \right)^2. \] (16)

We now repeat the foregoing calculations with four tones spaced by \( \Delta \omega \), each having an amplitude equal to \( N/8 \). As shown in Fig. 4, the tones are so chosen as to place their third-order intermodulation (IM) products in the adjacent channels. The output fundamentals and IM components have the following amplitudes: \( a = a_1 A + (15/2)a_3 A^3 \),

\[ b = a_1 A + 9a_3 A^3, \]

\[ c = (9/2)a_3 A^3, \]

\[ d = (9/4)a_3 A^3, \]

and \( e = (3/4)a_3 A^3 \). Adding the powers of the last three, we obtain the adjacent-channel power, which should then be normalized to the sum of the fundamental powers:

\[ \text{ACPR} = \frac{\left[ (9/2)^2 + (9/4)^2 + (3/4)^2 \right] a_3^2 A^6}{\left[ 2(a_1 A + (15/2)a_3 A^3)^2 + 2(a_1 A + 9a_3 A^3)^2 \right]} \] (17)

Since \( A = N/8 \), Eq. (8) yields

\[ \text{INL}_{\text{max},n} = \frac{32}{3\sqrt{3}} \left| \frac{a_3}{a_1} \right| A^2, \] (18)

and hence

\[ \text{ACPR} \approx \frac{23 \times 3^5}{214} \text{INL}_{\text{max},n}^2 (1 + 2.7 \text{INL}_{\text{max},n}), \] (19)

In a typical design, the denominator simplifies to approximately \( 2 - 5.36 \text{INL}_{\text{max},n} \), and

\[ \text{ACPR} \approx \frac{23 \times 3^5}{215} \text{INL}_{\text{max},n}^2 (1 + 2.7 \text{INL}_{\text{max},n}), \] (20)

\[ \approx 0.171 \text{INL}_{\text{max},n}^2 (1 + 2.7 \text{INL}_{\text{max},n}). \] (21)

For \( \text{INL}_{\text{max},n} \approx 10\% \) (25.6 LSBs for an 8-bit DAC), we observe from Eq. (23) that the four-tone test predicts an ACPR of \(-26.6\) dB, about \( 2.6\) dB higher than that of the two-tone test.

Figure 5 plots the ACPR for different tests using \( a_1 = 1.95 \times 10^{-2} \) and \( a_3 = 3.1 \times 10^{-7} \) and a progressively larger number of tones, where for \( n \) tones, the input amplitude of each is chosen equal to \( N/(2n) \). Here, \( \text{INL}_{\text{max},n} = 10\% \). We infer that \( n = 4 \) and hence Eqs. (21) and (23) provide a reasonable approximation of the ACPR. In other words, the ACPR is a function of the maximum input swing and \( \text{INL}_{\text{max},n} \), but relatively independent of the peak-to-average power ratio (PAPR = 2\( n \)), or the input power \( [P_{in} = 1/(2n)] \).

According to transistor-level simulations, the results shown in Fig. 5 change negligibly if the data transition times are varied from 10 ps to 20 ps or if random mismatches are included.

For circuit design purposes, we may be interested in the ACPR as a function of the output resistance of the unit current cell and the DAC resolution. Equations (9), (10), (20), and (23) readily afford such expression (Appendix II).

The foregoing derivations can be repeated if the DAC input does not reach its full scale. For \( A = \gamma (N/2) \), Eq. (23)
σ (or its rms value, significantly. We must therefore select the noise variance that “occasional” DAC overrange does not affect the ACPR amplitudes with a finite probability. We expect intuitively Gaussian input as the latter can assume arbitrarily large straightforward for a multi-tone signal but not for a white noise, where the DAC’s full scale is exercised. This scenario is simulations to check the accuracy of these equations. In order to investigate the robustness of ACPR \( \approx 0.171 (16\gamma^2) \text{INL}_{max,n}^2 (1 + 2.7 \text{INL}_{max,n}) \), we now allow the white-noise input variance to be greater than that of the four-tone test so that the DAC overranges more frequently. With \( \sigma = 1.2N/4 \), the overrange probability rises to 9.5%, but, as shown in Fig. 7, the disparity between the two types of tests still remains below 1 dB. We therefore conclude that for signals causing less than 10% overrange, the expression ACPR \( \approx 0.171 \gamma^2 \text{INL}_{max,n}^2 \) is reasonably accurate.

V. EFFECT OF PHASE DISTORTION IN CURRENT-MODE RF DACS

The static nonlinearity effect formulated in the previous sections is the principal contributor to the adjacent channel power. However, phase distortion also has some impact on the ACPR. For example, the drain-substrate junction capacitance of \( M_3 \) and \( M_6 \) in Fig. 1 varies considerably as the output voltage swings from near zero to well above \( V_{DD} \). In this section, we analyze this phenomenon.

For an intuitive understanding, we consider a DAC input of the form \( x(t) = r(t) \cos(\omega t) \), where \( r(t) \) denotes amplitude modulation (AM) and is the analog equivalent to \( k \) in Fig. 6. Since the bandwidth of \( r(t) \) is roughly equal to that of the
RF channel [19], we can assume that \( r(t) \) varies much more slowly than the carrier does. The average value of the drain junction capacitance is a function of \( r(t) \), causing the current-to-voltage transformation at the output node to experience a phase shift that depends on \( r(t) \). That is, the signal incurs AM/PM conversion in addition to AM/AM conversion:

\[
V_{\text{out}}(t) = \left[ a_1 r(t) + \frac{3}{4} a_3 r^3(t) \right] \cos[\omega_c t + \theta(t)],
\]

where \( \theta(t) \) denotes the phase corruption. We wish to relate the ACPR to \( \theta(t) \).

It is important to note that, in a fully-differential system, the envelope of Eq. (25) is an odd function of \( r(t) \), but the phase is an even function (Fig. 8). The evenness of the phase can be intuitively explained by the fact that the signal’s phase shift should be the same whether the differential input swing is \( +r \) or \( -r \).

For the DAC design example in Fig. 1, we can use simulations to construct the AM/AM and AM/PM characteristics. This is accomplished by transistor-level simulations in Keysight’s ADS, where a harmonic balance simulation is run for every digital input. Here, we have \( W/L = 5 \mu \text{m}/30 \text{ nm} \). Shown in Fig. 9, the plots provide the values of \( a_1 \) and \( a_3 \), and the maximum phase excursions. The phase, \( \theta(t) \), can be expressed as a “baseline” value of about 84° (not shown) plus a variable component, \( \theta_1(t) \), that reaches approximately \( \pm 6^\circ \):

\[
\theta(t) = 84^\circ + \theta_1(t).
\]

The baseline value does not play a role in the nonlinearity metrics, but \( \theta_1(t) \) is small enough to allow the approximations \( \cos \theta_1 \approx 1 \) and \( \sin \theta_1 \approx \theta_1 \). For the input and output voltage range of interest, we can model \( \theta_1 \) by an even function: \( \theta_1 = \beta_0 + \beta_2 r^2 \). For example, in the simulated AM/PM characteristic of Fig. 9(b), we have \( \beta_0 = -0.1 \text{ rad} \approx -5.5^\circ \) and \( \beta_2 = 0.2 \text{ rad} \approx 11^\circ \). While Fig. 9(b) implies that \( y = 5.5+11r^2\) is not an accurate approximation, we see below that it still provides a good estimate of the ACPR. It is helpful for our subsequent derivations to associate the \( \alpha_j \) terms to AM/AM conversion and the \( \beta_j \) terms to AM/PM conversion.

We should note that our formulation of phase distortion applies to different types of dynamic nonlinearity and even in the absence of static INL. As mentioned above, the nonlinear junction capacitance at the output nodes also lends itself to this analysis if memory effects are negligible, i.e., if the signal envelope does not contain rapid changes.

To calculate the ACPR, we first write the quadrature amplitudes of \( V_{\text{out}} \) in Eq. (25) as \( V_{\text{out},1} \cos(\omega_c t + 84^\circ) - V_{\text{out},q} \sin(\omega_c t + 84^\circ) \), where

\[
V_{\text{out},1} = (a_1 r + \frac{3}{4} a_3 r^3) \cos \theta_1
\]

\[
V_{\text{out},q} = (a_1 r + \frac{3}{4} a_3 r^3) \sin \theta_1
\]

\[
\approx (a_1 r + \frac{3}{4} a_3 r^3) \theta_1
\]

\[
\approx (a_1 \beta_0 + (a_1 \beta_2 + \frac{3}{4} a_3 \beta_0) r^3).
\]

The ACPR is equal to the power in the adjacent channel, i.e., that due to terms such as \( r^n, n \neq 1 \), divided by the power in the desired channel, i.e., that due to terms containing \( r^1 \):

\[
\text{ACPR} = \frac{\sum P_n}{P_1} \approx \frac{P_3}{P_1},
\]

where

\[
P_3 = P_{3,1} + P_{3,q}
\]

\[
= P_{3,1} \left[ 1 + \left( \frac{4 a_1}{3 a_3} \beta_2 \right)^2 \left( \frac{1}{1 + \beta_0^2} \right) \right]
\]

\[
\approx P_{3,1} \left[ 1 + \beta_0^2 + \frac{16}{9} \beta_0^2 \left( \frac{a_1}{a_3} \right)^2 \right],
\]

and

\[
P_1 = P_{1,1} + P_{1,q}
\]

\[
= P_{1,1} (1 + \beta_0^2).
\]

Equation (31) yields

\[
\text{ACPR} = \frac{P_{3,1}}{P_{1,1}} \left[ 1 + \left( \frac{4 a_1}{3 a_3} \beta_2 \right)^2 \left( \frac{1}{1 + \beta_0^2} \right) \right]
\]

\[
= 0.171 \text{ INL}_{\text{max},n}^2 \left[ 1 + \left( \frac{4 a_1}{3 a_3} \beta_2 \right)^2 \left( \frac{1}{1 + \beta_0^2} \right) \right].
\]

The first and second terms in the square brackets on the right hand side of Eq. (38) represent AM/AM and AM/PM ACPR mechanisms, respectively. Thus,

\[
\text{ACPR}_{P,M} = 0.171 \left( \frac{1}{6 \sqrt{3}} \left| \frac{a_3}{a_1} \right| N^2 \right) \left[ \left( \frac{4 a_1 \beta_2}{3 a_3} \right)^2 \left( \frac{1}{1 + \beta_0^2} \right) \right]
\]

\[
= 0.171 \left( \frac{2}{9 \sqrt{3}} \left| \frac{\beta_2}{\beta_0} \right| N^2 \right).
\]

We can therefore define

\[
\text{INL}_{\text{max},n,PM} = \frac{1}{6 \sqrt{3} \left( \frac{4}{3} \left| \frac{\beta_2}{\beta_0} \right| \right)} N^2,
\]

which, upon substitution in Eq. (38), leads to

\[
\text{ACPR} = 0.171 \text{ INL}_{\text{max},n}^2 + 0.171 \text{ INL}_{\text{max},n,PM}^2.
\]

For the RF DAC of Fig. 9, Eq. (42) predicts an ACPR of \(-26.2 \text{ dB} \) while transistor-level simulations show an ACPR of \(-26 \text{ dB} \), resulting in an error equal to \(0.2 \text{ dB} \).

While the foregoing results are based on simulations, our methodology and formulation can be applied to each specific DAC design so as to determine how AM/PM conversion translates to ACPR.
the digital input, \( m \). To compute the ACPR and relate it to the INL, we first introduce a general model for class-E circuits.

### A. Class-E RF DAC Model

Extensive efforts have been expended on modeling class-E stages [21], [22], [23], [24], [25], but the resulting equations are difficult to use for ACPR analysis. The lengthy expressions developed in the prior work arise due to the use of standard circuit analysis techniques such as Kirchhoff’s laws. We propose a new model that leads to general results and serves our purpose well.

Modeling a class-E DAC by a polynomial presents certain challenges. From the component values shown in Fig. 10, we recognize that, to the first order, the output power, \( P_{\text{out}} \), is independent of the total switch resistance. This means that \( P_{\text{out}} \) saturates as the DAC input reaches a certain level and the total on-resistance becomes sufficiently small. In other words, the output is saturated for a wide range of the digital input, making it difficult to approximate the behavior by a polynomial.

We begin by noting that the switch in Fig. 10 acts as a mixer, drawing a constant current from \( V_{DD} \) and upconverting it to the RF. We surmise that the switch, the RFC, and the supply voltage can be modeled by an RF Thevenin equivalent (Fig. 11). We must compute \( V_{\text{Thev}}, R_{\text{Thev}}, \) and the transfer function from \( V_{\text{Thev}} \) to \( V_{\text{out}} \). With the class-E component values, the transfer function reduces to

\[
\frac{V_{\text{out}}}{V_{\text{Thev}}} = \frac{0.43 - j0.5}{1 + Z_{\text{Thev}}(0.75 - j0.54)(P_{\text{sat}}/V_{DD}^2)} \tag{46}
\]

in the vicinity of the desired carrier frequency.

In the next step, we determine \( Z_{\text{Thev}} \). The time-variant nature of the network does not allow a direct analysis, but we can approach the problem as follows. We expect that \( Z_{\text{Thev}} \) is proportional to the switch resistance, \( R_{\text{on}} \), and write \( Z_{\text{Thev}} = \lambda R_{\text{on}} \). We then prove in Appendix III that the transfer function given by Eq. (46) is singular if \( R_{\text{on}} \approx -0.4 \Omega \). That is,

\[
1 + \lambda(-0.4 \Omega)(0.75 - j0.54)(P_{\text{sat}}/V_{DD}^2) = 0 \tag{47}
\]

and hence \( \lambda = 2.2 + j1.6 \) if \( P_{\text{sat}} = 1 \) W and \( V_{DD} = 1 \) V.

Thus,

\[
Z_{\text{Thev}} = (2.2 + j1.6)R_{\text{on}}. \tag{48}
\]

The complex value of \( Z_{\text{Thev}} \) is justified by noting that the time-variant circuit makes the Thevenin impedance a function of the load, as observed in N-path filters as well [26]. The transfer function then reduces to

\[
\frac{V_{\text{out}}}{V_{\text{Thev}}} = \frac{0.43 - j0.5}{1 + 2.5R_{\text{on}}(P_{\text{sat}}/V_{DD}^2)}. \tag{49}
\]

The last piece of this puzzle is \( V_{\text{Thev}} \). Since the maximum power delivered to the load, \( P_{\text{sat}} \), occurs with \( R_{\text{on}} = 0 \) and is given by \( |V_{\text{out}}|^2/(2R_L) \), we have from Eq. (49):

\[
\frac{|0.43 - j0.5|_2^2 |V_{\text{Thev}}|^2}{2R_L} = P_{\text{sat}}. \tag{50}
\]

Replacing \( R_L \) with \( 8/(\pi^2 + 4) \) \( V_{DD}^2 / P_{\text{sat}} \) gives

\[
|V_{\text{Thev}}| \approx 1.64 V_{DD}. \tag{51}
\]
Fig. 11. Model of a class-E RF DAC at \( f_c \).

Fig. 12. (a) AM/AM, and (b) AM/PM conversion for a class-E RF DAC.

B. INL of Switched-Mode Class-E DACs

Equation (52) permits us to compute the INL of class-E DACs as a function of the digital input, \( m \). The net output resistance is \( R_{on} = R_a/m \), where \( R_a \) denotes the resistance of a unit switching element. It follows that

\[
|V_{out}| = \frac{1.07 V_{DD}}{1 + 2.5(R_a/m)(P_{sat}/V_{DD}^2)}.
\]

In a manner similar to the calculation in Section II-A, we pass a straight line through the end points, subtract it from the characteristic, and differentiate the result with respect to \( m \). The maximum INL thus emerges as

\[
\text{INL}_{\text{max}} = \frac{1.07 V_{DD}\beta^2 N^2}{(\beta N + 1)(\sqrt{\beta N} + 1)^2},
\]

where \( \beta = 0.4 V_{DD}^2/(R_a P_{sat}) \) and \( N \) is the full-scale digital input. This value should be normalized to the maximum output voltage, \( |V_{out}(m = N)| \):

\[
\text{INL}_{\text{max,n}} = \frac{\beta N}{(\sqrt{\beta N} + 1)^2}.
\]

C. ACPR of Class-E RF DACs

For ACPR analysis, we consider a two-tone signal in the form of

\[
x_{in}(t) = A \sin \omega_m t \cos \omega_c t.
\]

The DAC can produce such an output if its overall switch conductance varies in proportion to the signal envelope while the phase of the LO switches between zero and \( \pi \):

\[
r_{on}(t) = \frac{R_{on}}{|\sin \omega_m t|},
\]

\[
\phi_{LO} = \begin{cases} 0, & 0 < \omega_m t < \pi, \\ \pi, & \pi < \omega_m t < 2\pi, \\ \end{cases}
\]

It follows from Eqs. (52) and (53) that

\[
V_{out}(t) = \frac{1.07 V_{DD}}{1 + 2.5R_{on}P_{sat}/V_{DD}^2} \times \cos \left[ \omega_c t + 0.22 \arctan \left( \frac{R_{on}}{\sin \omega_m t} \frac{P_{sat}}{1.5V_{DD}^2} \right) + 1 \right].
\]

It is possible to obtain the intermodulation products from the Fourier expansion of this equation, but the results are too complex to lead to a relation between the ACPR and the INL. For this reason, we resort to curve fitting for the ACPR:

\[
\text{ACPR} = 0.28 \left[ \left( \frac{R_{on}P_{sat}}{V_{DD}^2} \right)^{0.8} + 1 \right]^{1.25}.
\]

As shown in Fig. 13(a), the fit is fairly accurate for a wide range of \( R_{on} \). Moreover, the simulation results depicted in Fig. 13(b) indicate that increasing the number of tones beyond four has little effect on the ACPR. Our approach allows the designer to relate the nonlinearity and the ACPR by means of simple simulations.
Figure 14 repeats the simulations with different LO rise and fall times ($t_r$ and $t_f$, respectively), and with a sinusoidal LO. It is seen that the ACPR changes negligibly.

We repeat the white-noise test described in Section IV for switched-mode DACs as well, arriving at the behavior shown in Fig. 13(c). We conclude that white noise yields the same ACPR as an $N$-tone input if $\sigma_w = \frac{1}{2R_{on}}$ and

$$r_{on}(t) = \frac{2R_{on}}{w(t)}$$

where $w(t)$ denotes white noise with $\sigma_w = 1$.

It is interesting to compare this result to that obtained for current-steering DACs, namely, Eq. (23). As plotted in Fig. 15 for $\text{INL}_{\text{max},n} < 10\%$, the two ACPRs differ by as much as 16 dB for a given $\text{INL}_{\text{max},n}$ at low output power levels. The high ACPR arises because the switching action removes the amplitude variation due to baseband filtering.

This ACPR advantage of current steering accrues at the cost of power efficiency. In theory, class-A action yields a maximum efficiency of 50% for this architecture, whereas class-E operation, in principle, can approach an efficiency of 100% [20]. In practice, the former has been used in applications such as WCDMA [27], but the latter has also been embedded in linearity-correction loops with envelope tracking [28] or $\Delta \Sigma$ modulation [9].
waveform.

Fig. 16. (a) DAC model with time-variant output resistance, and (b) output waveform.

VII. Conclusion

This paper proposes simple expressions that allow the DAC designer to compute the ACPR from the INL. Both current-steering and switched-mode class-E DACs have been analyzed. The results have been studied by simulations that model the signal by multiple tones or white noise.

While our analysis has focused on current-steering (class-A) and switched-mode (class-E) architectures, other types of output stages can also be considered. For example, a class-D DAC design [29] can achieve a high efficiency with a nonlinearity similar to class-E. Another interesting candidate is the class-G stage [30], which deserves a thorough analysis and is beyond the scope of this paper.

APPENDIX I

Consider the simplified RF DAC model shown in Fig. 16(a), where the current source toggles between 0 and \( I_0 \), and its output conductance, \( g_O(t) \), between 0 and \( g_1 = 1/r_O \). We wish to compute the amplitude of the first harmonic of \( V_{\text{out}} \).

We note from Fig. 16(b) that, in the steady state, \( V_{\text{out}} \) jumps down to \( -V_1 \) when the current source turns off, charges for half of the period, jumps up to \( V_2 \) when the current source turns on, and charges for the other half. The time constants are given by \( \tau_1 = L_1/(R_L|g_L|^{-1}) \) and \( \tau_2 = L_1/R_L \). We must compute \( -V_1 \) and \( +V_2 \) and then find the Fourier coefficient of the first harmonic of this waveform. We can readily predict that

\[
V_{\text{out}} = -V_1 \exp\left(-\frac{t}{\tau_1}\right), \quad 0 < t < \frac{T}{2}
\]

\[
= V_2 \exp\left(-\frac{(t - T/2)}{\tau_2}\right), \quad \frac{T}{2} < t < T.
\]

Writing a KCL at the output node in Fig. 16(a) yields

\[
[g_L + g_O(t)]V_{\text{out}}(t) + I(t) + \frac{1}{L} \int_0^t V_{\text{out}}(\tau)d\tau = 0,
\]

where \( g_L = 1/R_L \). This equation must hold at \( t = T^-/2, T^+/2, T^- \), and \( T^+ \). Writing this equation at these times and combining the results, we obtain two equations in terms of \( -V_1 \) and \( V_2 \), from which we have

\[
V_1 = \frac{I_0}{g_1 + g_L} \exp\left[-T/2(\frac{1}{\tau_1} + \frac{1}{\tau_2})\right] - 1
\]

\[
V_2 = \frac{I_0}{g_L} \exp\left[-T/2(\frac{1}{\tau_1} + \frac{1}{\tau_2})\right] - 1.
\]

If the clock period is much shorter than the time constants, we have \( V_1 \approx V_2 \approx I_0/(g_1 + 2g_L) \). The amplitude of the first harmonic of the waveform in Fig. 16(b) is \((4/\pi)V_1\) and is computed as follows.

\[
\frac{4}{\pi}V_1 \approx \frac{4}{\pi} \frac{I_0}{g_1 + 2g_L} = \frac{2I_0}{\pi \left(\frac{1}{2r_O} + \frac{1}{R_L}\right)}
\]

\[
= \frac{2I_0}{\pi} [R_L||2r_O].
\]

APPENDIX II

We can obtain \( \alpha_1 \) and \( \alpha_3 \) from Eqs. (9) and (10) as follows:

\[
\alpha_1 = \frac{2I_0R_Lr_O \left(-R_L^2N^2 + 16R_LNr_O + 16r_O^2\right)}{(4r_O + R_LN) (4r_O + 3R_LN) (r_O + R_LN)}
\]

\[
\alpha_3 = \frac{4(4r_O + R_LN) (4r_O + 3R_LN) (r_O + R_LN)}{(4r_O + R_LN) (4r_O + 3R_LN) (r_O + R_LN)}
\]

Upon substitution in Eq. (20) and using the result in Eq. (23), we have

\[
\text{ACPR} = 0.171 \left(\frac{8\sqrt{3}R_L^2N^2}{9 \left(-R_L^2N^2 + 16R_LNr_O + 16r_O^2\right)}\right)^2 \times \left(1 + \frac{2.4\sqrt{3}R_L^2N^2}{-R_L^2N^2 + 16R_LNr_O + 16r_O^2}\right)
\]

APPENDIX III

In this appendix, we determine under what condition the class-E transfer function expressed by Eq. (46) becomes singular. Considering the model shown in Fig. 17(a) and assuming normalized values \( V_{DD} = 1 \) and \( P_{stat} = 1 \), we note that the high-Q resonator consisting of \( L_1 \) and \( C_1 \) is tuned to the carrier frequency, \( \omega_0 \), and rejects higher harmonics. We then approximate the admittance \( Y_L \) as

\[
Y_L(\omega) = \left\{ \begin{array}{ll}
(R_L + jL_1\omega)^{-1}, & \omega = \pm \omega_0, \\
0, & \omega \neq \pm \omega_0.
\end{array} \right.
\]

The admittance \( Y_0 \) thus emerges as

\[
Y_0(\omega) = \left\{ \begin{array}{ll}
\infty, & \omega = 0, \\
jC_p\omega + (R_L + jL_1\omega)^{-1}, & \omega = \pm \omega_0, \\
jC_p\omega, & \omega \neq \pm \omega_0.
\end{array} \right.
\]
then obtained as

\[
\begin{bmatrix}
g_0 + Y_{-N} & g_1 & \cdots & g_{-2N} \\
g_1 & g_0 + Y_{-N+1} & \cdots & g_{-2N+1} \\
\vdots & \vdots & \ddots & \vdots \\
g_{2N} & g_{2N-1} & \cdots & g_0 + Y_N \\
\end{bmatrix}
\begin{bmatrix}
a_{-N} \\
a_{-N+1} \\
\vdots \\
a_N \\
\end{bmatrix}
= -a_0
\begin{bmatrix}
g_N \\
g_{N-1} \\
\vdots \\
g_0 \\
\end{bmatrix}
\]  

(89)

Limiting the Fourier series in Eqs. (78) and (80) to \(N\) terms, we observe that Eq. (85) is valid for \(-N \leq n \leq +N, n \neq 0\). Now, we rewrite this system of \(2N\) equations and \(2N\) unknowns in a matrix form [Eq. (89)], as shown at the top of the page, or as

\[
MA = -V_{DD}G,
\]  

(86)

where \(M\) denotes the admittance matrix, and \(A\) the vector of \(a_k\)'s, and \(G\) the vector of \(g_k\)'s. Here, \(A\) is the unknown quantity. The transfer function is singular if the determinant of \(M\) is zero. Taking \(N = 4\) as an example, we set the determinant of \(M\) to zero, obtaining

\[
R_{on} \approx \frac{R_2^2 + L_2^2 \omega_0^2}{-2C_\mu L_2 \omega_0^2 + 2(L_s - C_\mu R_2^2) \omega_0 + 2R_L}
\]  

(87)

\[
\approx -0.4 \ \Omega
\]  

(88)

Higher values of \(N\) yield \(R_{on} \approx -0.4 \ \Omega\) as well. This result is confirmed by extending our circuit simulation to negative values of \(R_{on}\) (Fig. 18). For other values of \(V_{DD}\) and \(P_{sat}\), this critical \(R_{on}\) is simply scaled.
