Abstract—This paper reviews recent results from the UCLA Communication Systems Laboratory on the use of incremental redundancy. For channels with ACK/NACK feedback, this paper reviews how the transmission lengths used for communicating incremental redundancy should be optimized under the constraint of a limited number of incremental redundancy transmissions. For broadcast channels, this paper reviews optimization of the trade-off between packet-level erasure coding and physical-layer channel coding in the context of block fading with diversity that grows with blocklength.

I. INTRODUCTION

This invited talk reviews two results [1], [2] optimizing the use of incremental redundancy. In systems with feedback, incremental redundancy adapts the coding rate to the the accumulated information density (the “instantaneous capacity”) of the channel allowing the Shannon limit to be approached at much shorter average blocklengths than those required for the accumulated information density to concentrate around the Shannon capacity [3], [4], [5], [6], [7], [8]. In systems without feedback, incremental redundancy can provide a “fountain” of information from which a receiver need only “drink” what is needed to reliably identify the desired message [9], [10], [11]. For each of these two scenarios, this paper reviews optimization techniques that improve performance.

II. TRANSMISSION LENGTHS FOR ACK FEEDBACK

ACK/NACK feedback is non-active in the sense that the feedback does not change what is transmitted but rather only indicates whether additional transmissions are needed. For channels with ACK/NACK feedback, the sequential differential optimization (SDO) approach of [1] optimizes the transmission lengths used to communicate incremental redundancy. This optimization maximizes throughput under the constraint of a limited number of incremental redundancy transmissions.

A. The Normal Approximation

SDO utilizes the power of the normal approximation introduced in [3] that characterizes the behavior of the rate that a channel can support at finite blocklength. Following [3], define information density \( i(X,Y) \) as

\[
  i(X,Y) = \log_2 \frac{f_{Y|X}(y|x)}{f_Y(y)}.
\]

The expected value of \( i(X,Y) \) is the capacity of the channel. For the example of a BI-AWGN channel with noise \( z_k \),

\[
  i(X,Y) = 1 - \log_2 (1 + e^{-2(x_k + 1)/\sigma^2}) = i(z_k).
\]

The accumulated information density \( I_n \) at the receiver after \( n \) symbols is

\[
  I_n = \sum_{k=1}^{n} i(z_k).
\]

As pointed out by [3], (2) is a sum of independent random variables that will converge quickly to a normal distribution according to the central limit theorem, leading to the normal approximation of [3].

A key result of [1] is that a normal approximation also accurately describes the rate at which actual variable-length codes with incremental redundancy will successfully decode. Fig. 1 shows that for the NB-LDPC code used in [1] the empirical complementary cumulative distribution function on the rate at which decoding is successful is very closely approximated by a normal distribution for this example of the BI-AWGN channel with SNR of 2 dB. We have similarly confirmed the accuracy of the normal approximation to predict the rate at which decoding is successful for NB-LDPC codes in higher-SNR AWGN channels that require larger constellations and in fading channels with channel state information known at the receiver.
Fig. 1 shows that $R_S$ is well-approximated by a Gaussian with mean $\mu_S = E(R_S)$ and variance $\sigma_S^2 = \text{Var}(R_S)$:

$$f_{R_S}(r) = \frac{1}{\sqrt{2\pi\sigma_s^2}} e^{-\frac{(r - \mu_S)^2}{2\sigma_s^2}}. \quad (3)$$

The c.d.f. of the blocklength $N_S$ at which decoding is successful is $F_{N_S}(n) = P(N_S \leq n) = 1 - F_{R_S}(k/n)$. Taking the derivative of $F_{N_S}$ using the Gaussian approximation of $F_{R_S}$ produces the following “reciprocal-Gaussian” approximation for p.d.f. of $N_S$:

$$f_{N_S}(n) = \frac{k}{n^2 \sqrt{2\pi\sigma_S^2}} e^{-\frac{(\frac{k}{n} - \mu_S)^2}{2\sigma_S^2}}. \quad (4)$$

B. Sequential Differential Optimization

SDO uses the tight Gaussian approximation discussed above to optimize the sequence of blocklengths $\{N_1, N_2, \ldots, N_m\}$ to maximize the throughput. Suppose that the number of incremental transmissions is limited to $m$. An accumulation cycle (AC) is a set of $m$ or fewer transmissions and decoding attempts ending when decoding is successful or when the $m^{th}$ decoding attempt fails. If decoding is not successful after the $m^{th}$ decoding attempt, the accumulated transmissions are forgotten and the process starts over with a new transmission of the first block of $N_1$ symbols. From a strict optimality perspective, neglecting the symbols from the previous failed AC is sub-optimal. However, the probability of an AC failure is sufficiently small that the performance degradation is negligible. Neglecting these symbols greatly simplifies analysis.

The cumulative blocklength $N_j$ at the $j$th stage is simply the sum of the first $j$ increment lengths. Using the p.d.f. of $N_S$ from (4) we can compute the probability that the decoder will need a particular incremental transmission. For $N_j < N_{j+1}$, the probability of a successful decoding attempt at blocklength $N_{j+1}$ but not at $N_j$ is

$$f_{N_{j+1}}(n)dn = \int_{N_j}^{N_{j+1}} \frac{k}{n^2 \sqrt{2\pi\sigma_S^2}} e^{-\frac{(\frac{k}{n} - \mu_S)^2}{2\sigma_S^2}} dn \quad (5)$$

$$= Q\left(\frac{r_{j+1} - \mu_S}{\sigma_S}\right) - Q\left(\frac{r_j - \mu_S}{\sigma_S}\right). \quad (6)$$

where $r_j = k/N_j$.

Define the throughput as $R_T = \frac{E[N]}{E[N]}$, where $E[N]$ represents the expected number of channel uses and $E[K]$ is the effective number of information bits transferred correctly over the channel. The expression for $E[N]$ is

$$E[N] = N_1 Q\left(\frac{k}{N_1} - \frac{\mu_S}{\sigma_S}\right) + \sum_{j=2}^{m} N_j \left[ Q\left(\frac{k}{N_j} - \frac{\mu_S}{\sigma_S}\right) - Q\left(\frac{k}{N_{j-1}} - \frac{\mu_S}{\sigma_S}\right)\right] + N_m \left[ 1 - Q\left(\frac{k}{N_m} - \frac{\mu_S}{\sigma_S}\right)\right]. \quad (7)$$

The first term (7) shows the contribution to the expected blocklength from successful decoding on the first attempt. $Q\left(\frac{k}{\sigma_S} - \frac{\mu_S}{\sigma_S}\right)$ is the probability of decoding successfully with the initial block of $N_1$. Similarly, the terms in the summation of (8) are the contributions to the expected blocklength from decoding that is first successful at total blocklength $N_j$ for $j \geq 2$ (at the $j^{th}$ decoding attempt). Finally, the contribution to expected blocklength from not being able to decode even at $N_m$ is (9). Even when the decoding has not been successful at $N_m$, the channel has been used for $N_m$ channel symbols. The expected number of successfully transferred information bits $E[K]$ is

$$E[K] = kQ\left(\frac{k}{N_m} - \frac{\mu_S}{\sigma_S}\right), \quad (10)$$

where $Q\left(\frac{k}{\sigma_S} - \frac{\mu_S}{\sigma_S}\right)$ is the probability of successful decoding. Note that $E[K]$ depends only on $k$ and $N_m$. In fact, $E[K] \approx k$ and is not sensitive to the specific choice of $N_m$ for reasonably large values of $N_m$.

The initial blocklength is $N_1$ and we seek the optimal blocklengths $\{N_1, N_2, \ldots, N_m\}$ to maximize the throughput. Over a range of possible $N_1$ values, the SDO technique introduced in [1] selects $\{N_2, \ldots, N_m\}$ to minimize $E[N]$ for each fixed value of $N_1$ by setting derivatives to zero as follows:

$$\frac{\partial E[N]}{\partial N_j} = 0, \quad \forall j = 1, \ldots, m-1. \quad (11)$$

For each $j \in \{2, \ldots, m\}$, the optimal value of $N_j$ is found by setting $\frac{\partial E[N]}{\partial N_{j-1}} = 0$, yielding a sequence of relatively simple computations. In other words, we select the $N_j$ that makes our previous choice of $N_{j-1}$ optimal in retrospect.

For $j > 2$, $\frac{\partial E[N]}{\partial N_{j-1}} = 0$ depends only on $\{N_{j-2}, N_{j-1}, N_j\}$ as follows:

$$\frac{\partial E[N]}{\partial N_{j-1}} = Q\left(\frac{k}{N_{j-1}} - \frac{\mu_S}{\sigma_S}\right) - Q\left(\frac{k}{N_{j-2}} - \frac{\mu_S}{\sigma_S}\right).$$

Thus we can solve for $N_j$ as

$$N_j = Q\left(\frac{k}{N_{j-1}} - \frac{\mu_S}{\sigma_S}\right) + N_{j-1} Q\left(\frac{k}{N_{j-2}} - \frac{\mu_S}{\sigma_S}\right) - Q\left(\frac{k}{N_m} - \frac{\mu_S}{\sigma_S}\right). \quad (12)$$

For each possible value of $N_1$, SDO can be used to produce an infinite sequence of $N_j$ values that solve (11) for any choice of $m$. The sequence does not depend on $m$, only $N_1$. Each such sequence is an optimal sequence of increment lengths for a given density of decoding attempts on the time axis. As $N_1$ increases, the density of decoding attempts decreases, lowering system complexity. Using SDO to compute the optimal $m$ decoding points is equivalent to selecting the most dense SDO-optimal sequence that when truncated to $m$ points still meets the frame-error-rate target.
C. Approaching Capacity at Short Blocklengths with Feedback

Fig. 2 shows the resulting throughputs obtained by using SDO to find the optimal incremental lengths for values of \( m \) in the range of 2 < \( m \) < 20 for the target FER of 10^-3 for the NB-LDPC code of [1] for \( k = 96 \) message bits. Fig. 2 illustrates that with \( m = 10 \) decoding points, a system can closely approach the performance of a system that has \( m = \infty \), which is the limiting case where decoding is attempted and feedback of an ACK/NACK is required after every received symbol.

Using SDO, variable-length codes with average blocklengths of around 500 symbols can closely approach capacity in theory and in practice as demonstrated in [1]. Fig. 3 illustrates the example of a binary-input (BI) additive white Gaussian noise (AWGN) channel with frame error rate (FER) required to be less than 10^-3. For a system transmitting \( k \) symbols at an average blocklength of \( \lambda \), the throughput \( R_t \) is defined by \( R_t = k/\lambda \). For reference, Fig. 3 shows the curves of possible throughput \( R_t \) as a function of \( \lambda \) for some values of \( k \). The performance characterization for fixed-blocklength codes is from [3] and is based on the normal approximation, which is shown in [3] to be accurate for blocklengths as small as 100 symbols.

The computation of the random coding lower bound on the performance of variable-length codes with feedback is based on the analysis in [4].

Fig. 3 shows curves from [1], [5], [6] that show simulation results that approach or exceed the performance promised by [4] in the range of average blocklengths below 500 bits. For values of \( k = 16, k = 32, k = 64, \) and \( k = 89 \) these throughput results exceed Polynskiy’s random coding lower bound. As the average blocklength becomes larger, the random coding lower bound is more predictive.

III. PACKET-LEVEL VS. PHYSICAL LAYER REDUNDANCY

Consider a broadcast setting that uses a hybrid of packet-level erasure coding and physical layer coding to provide a stream of information with the goal of each receiver decoding the desired message at the earliest opportunity. There is a trade-off between using available redundancy for additional packets in a packet-level erasure code or simply for additional physical-layer code symbols.

As the amount of available redundancy grows, the work of [12] shows that in several different block fading scenarios the physical layer coding rate decreases ultimately to zero while the packet-level erasure coding rate does not. This indicates that at some point incremental redundancy should be directed to the physical layer rather than additional packet-level erasure coding. This paper reviews the recent work [2] that studies the this hybrid coding approach using a proportional diversity block fading model (in which diversity increases linearly with blocklength).

A. The Channel Model and Optimization Problem

Consider a transmitter and a receiver communicating over a fading channel [13]. The one-dimensional channel is modeled as \( Y = HX + Z \) where \( X \) is the transmitted symbol, \( Y \) is the received symbol, \( H \) is the fading coefficient, and \( Z \) is i.i.d. additive white Gaussian noise (AWGN) with variance \( \sigma^2 \) and mean 0. We assume the channel is Rayleigh with \( E[H^2] = 1 \), \( Z \) has unit variance, i.e. \( \sigma^2 = 1 \). Let the average transmit power be \( E[X^2] = P \). Then, the instantaneous signal-to-noise ratio (SNR) when \( H = h \) is \( h^2P \). For this Rayleigh fading channel, SNR (denoted \( \gamma \)) is exponentially distributed.
with parameter $\frac{1}{T}$ that depends only on the average transmit power. Note that, $\gamma$ has a mean of $P$.

A message consisting of $m$ packets with $k$ nats of information per packet is to be transmitted with a low probability of message error $q$; this is the probability that the receiver fails to recover all the $m$ packets. The transmitter uses the channel for $T$ units of time for an overall code rate of $\frac{mk}{T}$. It performs erasure coding across the $m$ packets at a rate $R_E$ and codes each resultant packet at a channel-coding rate $R_C$ such that

$$\frac{mk}{T} = R_E R_C.$$  

That is, the $m$ packets are first coded using an erasure code at rate $R_E$ to yield $\frac{mk}{T}$ packets. Note that, for erasure coding, $R_E$ has to satisfy $R_E \leq 1$. To transmit each packet, the transmitter uses a channel code at rate $R_C$ [nats/ channel-use] so that the resultant codeword block-length of each packet is $\frac{k}{R_C}$. For a fixed average transmit power, our objective is to pick the value of $R_C$ (and thus $R_E$) that optimizes an objective function. The unit of channel-coding rate is “nats/ channel-use” for convenience. The receiver is assumed to know the fading coefficient $H$ while the transmitter does not.

The proportional diversity (PD) model introduce a parameter $l_f$, which describes the length of a fade. With the block-length being $\frac{k}{R_C}$, the number of block fades $F_p$ in a transmitted codeword of a system with PD block fading of fade lengths $l_f$ is

$$F_p = \left\lceil \frac{k}{R_C l_f} \right\rceil.$$  

With PD block fading, long codewords benefit from an inherit increase in diversity. For this work, we assume that each block-fading event is independent, i.e. $H$ assumes i.i.d. values across different block fades.

The receiver sees $\frac{k}{R_C} = R_TCk^{-1}$ packets from the channel. The number of packets that the decoder of the erasure code requires to recover the message, denoted $\hat{m} \geq m$, depends upon the erasure code. For Reed-Solomon erasure codes, $\hat{m} = m$; for fountain codes such as a Raptor code, $\hat{m} > m$ typically.

Thus, the probability of message error $q$ can be written using the binomial distribution as

$$q = \sum_{i=0}^{\hat{m}-1} \binom{R_C Tk^{-1}}{i} (1 - p_e)^i p_e^{R_C Tk^{-1} - i}.$$  

In the above expression, $p_e$ denotes the probability that a packet is not decoded successfully (and declared an erasure) upon reception from the channel; this is called the probability of packet erasure. Owing to our assumption that the channel codes in the system operate close to capacity with zero block-error probability when the Shannon capacity exceeds the attempted rate, $p_e$ constitutes only one event: fading outage [14].

The binomial sum in (15) can be computed numerically only for small values of $R_C Tk^{-1}$. Hence, we approximate the random variable that denotes the number of packets successfully decoded by the channel decoder using the Central Limit Theorem (CLT), and obtain the Gaussian approximation for $q$ [12] as

$$q \approx \Phi \left( \frac{(\hat{m} - 1) - R_C Tk^{-1} (1 - p_e)}{\sqrt{R_C Tk^{-1} p_e (1 - p_e)}} \right),$$  

where $\Phi(x)$ is the value of the c.d.f. of the standard normal random variable at $x \in \mathbb{R}$.

To summarize, the objective is to minimize the message-error probability $q$ in (15) via (16), where $p_e$ is also a function of $R_C$. Writing the minimization problem in terms of $R_C$, $R_E$ can be obtained as $R_E = \frac{mk}{T R_C}$. Hence, the optimization problem is as follows:

$$\min_{R_C} \Phi \left( \frac{(\hat{m} - 1) - R_C Tk^{-1} (1 - p_e)}{\sqrt{R_C Tk^{-1} p_e (1 - p_e)}} \right),$$  

subject to $p_e (R_C) = \mathbb{P} \left[ \frac{k}{R_C l_f} \sum_{i=1}^{k} C(\gamma_i) + \frac{k}{R_C l_f} C(\gamma_{last}) < (1 + \epsilon) R_C \right], \frac{k}{T} \leq R_C \leq \frac{k}{l_f}, R_C Tk^{-1} \in \mathbb{N}.$  

(17)

Note that, minimizing $\Phi(\cdot)$ is equivalent to minimizing its argument, and the value of $q$ need not be explicitly computed. We have specified the dependence of $p_e$ on $R_C$ here for clarity.

As noted in [12], [15], and many previous works, the evaluation of $p_e$ for the block-Rayleigh fading channel (or for its PD version) is not a straightforward task. One can use [15] or similar works for the block-Rayleigh fading channel to compute the outage probability $p_e$ with a miniscule error. But, our fading model complicates it further as we have a sum of two random variables that are not identically distributed in the expression for $p_e$ in (17). We first expand and rearrange the terms in $p_e$ for our one-dimensional PD block-Rayleigh fading channel with capacity-achieving codes to obtain

$$p_e = \mathbb{P} \left[ \sum_{i=1}^{k} W_i + \left( \frac{k}{R_C l_f} - \frac{k}{R_C l_f} \right) W_{last} < \frac{ck}{l_f} \right],$$  

where $c = 2(1 + \epsilon)$, $W_i = \log(1 + \gamma_i)$, $W_{last} = \log(1 + \gamma_{last})$.

**B. Gaussian Approximations of the Optimization Problem**

Based on Gaussian approximations of $p_e$ in (18), as inspired by [12], [2] presents four approximations to the optimization problem (17). For numerical-search based results, [2] uses a very low value of the margin, say $\epsilon = 0.05$, to obtain $c$.

1) Gaussian Approximation 1 (Approx. 1): Ignoring the contribution of $W_{last}$ in (18), we get

$$p_e = \mathbb{P} \left[ \sum_{i=1}^{k} W_i < \frac{ck}{l_f} \right].$$  

(19)
The above can be approximated using the Gaussian CDF as
\[ p_e = \Phi \left( \frac{c_{R_{CE}} - \mu(P)}{\sqrt{\frac{k}{R_{Cf}l_f} \text{Var}(P)}} \right). \tag{20} \]

The values of \( \mu(P) \) and \( \text{Var}(P) \), which denote the mean and variance of \( \log(1 + \gamma) \) with \( \gamma \sim \text{Exponential} \left( \frac{1}{l_f} \right) \), can be computed as stated in [12]. By ignoring the flooring function, we get Gaussian approximation 1 (Approx. 1), which is an adaptation of (19) in [12] to PD block-Rayleigh fading:
\[ p_e = \Phi \left( \sqrt{\frac{k}{R_{Cf}l_f}} \frac{c_{R_{CE}} - \mu(P)}{\text{Var}(P)} \right). \tag{21} \]

2) Gaussian Approximation 2 (Approx. 2): For Approx. 2, we evaluate (20) directly. The approximation to \( p_e \) that is being made here is imprecise in the sense that, (20) evaluates to the same value for a range of \( R_{CE} \) values; the reason being the presence of the flooring function.

3) Gaussian Approximation 3 (Approx. 3): This approximation is the evaluation of (18) with a constrained search space that limits \( R_{CE} \) such that both \( \frac{m}{c_{R_{CE}}} \) and \( \frac{k}{R_{Cf}l_f} \) are positive integers.

4) Gaussian Approximation 4 (Approx. 4): The Gaussian approximation that we make here considers both the terms in (18), making it the most appropriate. Once we find out \( \mu(P) \) and \( \text{Var}(P) \), we assume that \( \sum_{i=1}^{n} \frac{1}{l_f} \) \( W_i \) is Gaussian and also that \( \left( \frac{k}{R_{Cf}l_f} - \frac{k}{R_{Cf}l_f} \right) W_{\text{int}} \) is Gaussian. Thus, their linear sum is another Gaussian random variable denoted \( W_G \), which stands for Gaussian approximation of weighted average mutual information, with
\[ \text{mean}(W_G) = \frac{k}{R_{Cf}l_f} \mu(P), \]
\[ \text{Var}(W_G) = \text{Var}(P) \left[ \frac{k}{R_{Cf}l_f} + \left( \frac{k}{R_{Cf}l_f} - \frac{k}{R_{Cf}l_f} \right)^2 \right]. \tag{22} \]

Thus, \( p_e \) for this approximation (Approx. 4) is
\[ p_e = \Phi \left( \frac{c_{R_{CE}} - \text{mean}(W_G)}{\sqrt{\text{Var}(W_G)}} \right). \tag{23} \]

C. Results and conclusions

Fig. 4 shows an example of the optimal values of \( R_{CE} \) and \( R_E \) obtained from Approximations 1 and 4 as the overall code rate \( \frac{mk}{T} \) goes to 0. As observed by Courtade and Wesel [12] for the (fixed diversity) block-fading channel, for the PD block-fading model that the optimal channel-coding rate goes to 0. However, where the optimal value of \( R_E \) approached a non-zero constant less than 1 for fixed diversity in [12], under PD block-fading it is approaching 1. With sufficient overall redundancy, packet-level erasure coding is unnecessary in a block fading channel with proportional diversity. Note that rate-compatibility in this scenario is challenging because the rate \( R_E \) increases for a sufficiently low overall rate.
