days, one for a month, and two for six months. The samples were dissolved in warm nitric acid. Aliquots were evaporated with ruthenium metal carrier, and fused with a KOH—KNO₃ mixture to ensure exchange between fission product and carrier. The ruthenium was then converted to RuO₄ by periodate oxidation and purified by distillation and solvent extraction.

The Ba¹⁴⁹ activities in the 7-day and one-month irradiations were determined by the method of Glendenin and Steinberg, modified by Cook. The Cs¹³⁷ activities in the six-month irradiations were determined by J. G. Cuninghame and M. Sizeland, using a perchlorate separation followed by β counting.

From the saturation activities, the fission yields of Ru¹⁰⁰ and Ru¹⁰⁴ were calculated relative to Ba¹⁴⁹ for the seven-day and one-month irradiations. The fission yield of Ba¹⁴⁹ was taken to be 6.2 percent. The saturation activities for Ru¹⁰⁰ and Cs¹³⁷ were calculated for the 6-month irradiation, and assuming a fission yield of 6.15 percent for Cs¹³⁷, the fission yield of Ru¹⁰⁰ was found. The values obtained are given in Table I.

<table>
<thead>
<tr>
<th>Irradiation period</th>
<th>7 days</th>
<th>1 month</th>
<th>6 months</th>
</tr>
</thead>

<tr>
<td>Fission yield Ru¹⁰⁰</td>
<td>2.8</td>
<td>2.9</td>
<td>—</td>
</tr>
<tr>
<td>Fission yield Ru¹⁰⁴</td>
<td>0.37</td>
<td>0.38</td>
<td>0.38</td>
</tr>
</tbody>
</table>

The probable error in the determination of the value for Ru¹⁰⁰ is ± 5.7 percent and for Ru¹⁰⁴ ± 7.6 percent. These errors are largely due to the uncertainties in the fission yields of Ba¹⁴⁹ and Cs¹³⁷ and the half-lives of Ru¹⁰⁰ and Cs¹³⁷.

Thus, the value for the percentage fission yields were found to be 2.85 ± 0.16 for Ru¹⁰⁰ and 0.35 ± 0.03 for Ru¹⁰⁴. They are lower than Glendenin and Steinberg's values which were 3.7 and 0.52 for Ru¹⁰⁰ and Ru¹⁰⁴. In both determinations the ratio of the Ru¹⁰⁰ and Ru¹⁰⁴ yields is nearly the same, being approximately seven.

I am grateful to Dr. J. M. Fletcher for suggesting this work and to him and Dr. G. B. Cook for most helpful discussions; also to the Director of the Atomic Energy Research Establishment, Harwell, for permission to publish this letter. Full details are being given in Atomic Energy Research Establishment Report C/R 1180.

The Total $\pi^– - p$ Cross Section at 840 and 470 Mev

A. M. Shapiro, C. P. Leavitt, and F. F. Chen
Brookhaven National Laboratory, Upton, New York
(Received September 10, 1953)

The total $\pi^– - p$ cross section has been measured at 840 Mev.

Since this value appeared considerably higher than that measured at 480 Mev, the measurement was repeated at the lower energy to confirm the difference with the same experimental arrangement and apparatus.

The experimental arrangement is shown in Fig. 1. A Be target, 6 in. X 2 in. X 2 in., was placed in a straight section of the Brookhaven cosmotron and bombarded by 2.2-Bev protons. Particles emitted from the target at an angle of 32° to the proton direction passed through a 3-in. diameter collimator in the concrete shielding wall.

This beam was then magnetically analyzed, and particles of the proper sign and momentum entered a threefold defining telescope.
effects which are different for the two geometries. The value of \( \sigma \) (poor) is low because some products of the \( \pi^- - \rho \) interaction will pass through the last counter. On the other hand, \( \sigma \) (good) is high because a few more mesons are multiply scattered out of the last counter by the CH\(_2\) than by the C attenuator, when the “good” geometry is used. We have assumed that 3 percent of the \( \pi^- - \rho \) interactions give a charged secondary traveling within 6.6° of the beam direction, and 0.3 percent within 2.1°. This corresponds to the condition that all the interactions are elastic scatterings with an isotropic distribution in the center-of-mass system, or to the condition that \( \frac{3}{4} \) of the interactions are elastic scatterings with a cos\(^2\) distribution and that the rest send no charged products into the last counter. From a detailed multiple Coulomb scattering calculation it was found that about 9 and 7 percent of the mesons were scattered out of the last counter by the CH\(_2\) and C absorbers, respectively, in the “good” geometry position, while no mesons were so lost in the “poor” geometry position. With these corrections the value of \( \sigma \) for both geometries becomes 47 mb. Thus the total \( \pi^- - \rho \) cross section is 47.5 \pm 5 mb for a mean energy in the absorber of 840 Mev. The stated error includes an estimate of the uncertainties in the corrections.

We have repeated the above measurements with 500-Mev incident mesons using mainly the 6.6° geometry. With similar corrections, the total \( \pi^- - \rho \) cross section was found to be 27 \pm 5 mb for a mean pion energy of 470 Mev. This agrees well with the value of 25 \pm 3 mb at 450 Mev found previously at this laboratory.\(^1\)

We find therefore a rise of approximately 20 mb in the total \( \pi^- - \rho \) cross section from 470 to 840 Mev. Since the cross section has been found to be 34 \pm 3 mb at 1.5 Bev,\(^4\) and, very recently, 47 \pm 4 mb at 1.0 Bev,\(^4\) a second peak in the neighborhood of 900 Mev is indicated. Further study of this energy region has been undertaken by Lindenbaum and Yuan, and Piccioni and Cool.

We should like to thank Dr. George B. Collins and Professor J. Steinberger for their important roles in the initial stages of this experiment, and the many members of the cosmotron group who made it possible.

Evidence for Subshell at \( Z = 96 \)

GLENN T. SEABORG  
Radiation Laboratory and Department of Chemistry, University of California, Berkeley, California  
(Received September 18, 1953)

THE evidence is decisive that major nuclear shells are completed at 82 protons and 126 neutrons (both represented by the nuclide Pb\(^{208}\)) and these, along with major shells at 82 neutrons and certain lower nuclide numbers (\( N = 20, 28, 50 \)), are well explained by the strong spin-orbit coupling model of Mayer\(^6\) and Haxel, Jensen, and Suss.\(^3\) This model suggests the filling of quantum states at certain intermediate points, and there is an accumulating amount of evidence that such “subshells” are also discernible, for example, at \( Z = 58 \) and \( Z = 64 \).\(^5\)

The evidence from alpha radioactivity, both (1) the effect of the nuclear radius shrinkage on the relationship between energy and half-life and (2) the discontinuities in the plots of energy vs mass number at constant \( Z \), gives a striking indication\(^8\) of the closing of major shells at \( Z = 82 \) and \( N = 126 \). Application of these sensitive criteria as tests for the much smaller “subshell” effects in the regions \( Z > 82 \) and \( N > 126 \) leads to some evidence for such a subshell at \( Z = 96 \) (curium).

Since it has been shown that the Gamow-Gurney-Condon type of formula for alpha decay applies very well to the ground state to ground state transition for even-even alpha emitters,\(^8\) the known\(^9\) alpha energies and partial half-lives were used in the Preston\(^6\) form of the formula to calculate the nuclear radii of a number of even-even nuclides in the range \( Z = 84 \) to 98. Using these radii, a value of \( r_{2\pi} \) was calculated for each nuclide from the relationship \( r_{2\pi} = \frac{r_{5/2}}{2} \) and the plot in Fig. 1 of the average value of \( r_{2\pi} \) (\( r_{2\pi} \) generally decreasing with increasing \( Z \)) for each element indicates a just discernible minimum or plateau at \( Z = 96 \). The average value of \( r_{2\pi} \) for each element was plotted because there is no discernible regular variation of \( r_{2\pi} \) with \( A \) at constant \( Z \).

The stable shell of 82 protons is attained upon completion of the \( h_{11/2} \) level and the spin of Bi\(^{209} \) (9/2) indicates that the 83rd proton begins the filling of the \( h_{11/2} \) level as might be expected. However, if the \( h_{11/2} \) level is raised in energy as more protons are added, so that the \( f_{7/2} \) and \( f_{5/2} \) are filled before the \( h_{11/2} \) levels, one might expect subshell effects at \( Z = 90 \) and 96. If the quantum states are filled in this order, the variation of \( r_{2\pi} \) with \( Z \) should perhaps also indicate an effect \( Z = 90 \). A careful consideration of the values of \( r_{2\pi} \) in the region on both sides of \( Z = 90 \) points to a barely discernible plateau in the variation of \( r_{2\pi} \) with \( Z \) at this atomic number.

In the case of \( Z = 96 \) there is an additional argument which points to the completion of a subshell here. The known odd-even isotopes of beryllium, Bi\(^{208}\) and Bi\(^{210}\), are highly “hindered” in their most prominent modes of alpha decay, i.e., they decay much slower than the simple formula would indicate. This exceptional degree of hindrance is not observed for similar (odd-even) isotopes of any other odd \( Z \) alpha-particle emitter with the exception of bismuth (\( Z = 83 \)) where the slowed rates of decay are presumably to be associated with the closed proton shell (and consequent shrunked radius) at \( Z = 82 \).

There are other lines of evidence which may also point to the filling of the \( f_{7/2} \) and \( f_{5/2} \) before the \( h_{11/2} \) proton states. The spins of Np\(^{237}\) 11 and Am\(^{242}\) 12 are both 5/2 as expected on this basis. On the other hand, the spins of Ac\(^{237}\) 14 and Pa\(^{239}\) 14 have both been reported as 3/2, indicating perhaps that the odd proton occupies the \( h_{11/2} \) state, whereas spins of 7/2 and 5/2 corresponding to \( f_{7/2} \) and \( f_{5/2} \) states, respectively, would be expected. Whether or not this indicates a breakdown of the single-particle model, it does seem to indicate that arguments based on spin values cannot be conclusive here. It is interesting to add that a consideration of the systematics of beta radioactivity in this region also leads to the assignment of spectroscopic states in agreement with the suggested higher position of the \( h_{11/2} \) level energetically.

It is interesting to note that arguments based on spin values\(^2\) indicate that in the case of neutrons the \( f_{7/2} \) level fills before the \( h_{11/2} \) level just after the completion of the major shell at 82 neutrons. Thus, the situation is analogous to that postulated for protons although the evidence is not clear on the relative position of the \( f_{5/2} \) and \( h_{11/2} \) neutron levels.
